SUMMARY

The following are discussed in relation to the sleep EEGs of infants and young children:

1. the normal patterns of sleep and changes in them, during the first few months of life;
2. the characteristics of normal paroxysmal (arousal) phenomena, drowsy hypersynchrony and encoches frontales;
3. criteria for abnormality;
4. some recording considerations.

OPSOMMING

Die volgende is bespreek ten opsigte van die slaap-EEGs van babas en jong kinders:

1. die normale slaap patrone en veranderinge gedurende die eerste paar maande;
2. die eienskappe van normale paroksismale tekens van opwekking, hipersinchronie gedurende duiseligheid en encoches frontales;
3. kriteria om abnormaliteit te bepaal;
4. oorwegings in verband met EEG-opname.

LIST OF TABLES AND FIGURESTABLES

There is general agreement that the analysis of the EEGs of sleeping infants and young children is fraught with hazards, particularly for the unwary and inexperienced. Many factors contribute to the difficulties encountered. One, for example, is the immaturity of the central nervous system. The rapid development of the cortex is reflected in the marked changes that occur in the electrical activity recorded by the EEG, particularly during the first few months of life. By its nature, also, the recording situation adds to the complexities of analysis. Children and infants who are unable or unwilling to comprehend what is required must be sedated. The alternative to this is to wait until natural sleep supervenes. However, in a busy clinical practice this is not always feasible, and some form of sedation is usually necessary. Many of the commonly used sedatives produce beta (fast) activity in the EEG which is generalised and usually maximal in the fronto-centro-temporal area. (Figure 1). Although this can be predicted and allowed for during EEG analysis, very often the combination of drug-induced beta activity, and the fast (spindle) activity normally occurring during sleep leads to the production of activity of sharp-tipped (spike) appearance. (Figure 2). Differentiation between the latter and epileptiform activity is not always possible. Further, sedating the child to induce sleep which is rapid may suppress epileptiform discharges. It is not always possible to judge the optimal sedative dosage with precision. These factors excepted, however, the use of sedation to induce sleep in children in the clinical EEG laboratory is an accepted and widespread practice, based on the demonstrated lack of significant differences in EEG patterns resulting from this practice and those during natural daytime sleep. A prime difficulty lies in distinguishing between the normal phenomena (paroxysmal) of sleep, and epileptogenic activity. This implies that some sort of knowledge of what is normal in the sleep EEGs of children is necessary.

## W H A T I S N O R M A L ?

### A. SLEEP PATTERNS

FIGURE 1                      Very considerable beta activity induced in a sedated male, aged 14 months, referred for EEG examination.    Probably Stage 1 sleep. Patient was not on medication.    Sedation was induced by 1 Vesparaxette suppository.

FIGURE 2            The combination of beta activity (high voltage) induced by sedation and sleep spindles particularly in frontal areas produces a spike-like effect. The patient was a male, 21 months, sedated by a Vesparaxette suppository. Normal EEG.

By the 8th month of intra-uterine life the EEG reflects changes related to the sleep/wakefulness cycle. Increases in amplitude of the slowest waves of the EEG, particularly in the posterior cortical areas, occur during sleep. At term, Anders and his coworkers (1971)<sup>1</sup> suggest that 3 sleep states are distinguishable, and have provided criteria for their scoring. Briefly, these are as follows:

1. ACTIVE SLEEP (AS). This corresponds to REM sleep in the adult. Activity prevails during this state. The infant's respiration is irregular, his facial expressions change, and digit, limb and body movements occur. Chin EMG is absent. REMs are present. The EEG shows low voltage irregular fast theta activity (dominant frequency of 5 - 8 Hz). This may be superimposed on high voltage slow activity, or the latter may rarely be seen alone.
2. QUIET SLEEP (QS). The adult equivalent of this is slow wave sleep (SWS). Behavioural quiescence with no body movements is typical. Chin EMG is increased. Respiration is regular and REMs are absent. The EEG shows trace alternant or high voltage slow activity (0,5-3 Hz). (Figure 3). Trace alternant is characterised by bursts of HVS, at times intermixed with sharp waves, with periods of intervening relative quiescence.
3. INTERMEDIATE SLEEP (IS). The characteristics of this state do not permit classification as either AS or QS. This is also termed transitional sleep, and occurs at sleep onset, when states are changing, or during arousal.

Ellingson and Peters (1980a)<sup>2</sup> suggest that in normal infants the following maturational changes occur during daytime sleep in the first few weeks of post-term existence.

1. Trace alternant activity disappears. This pattern is seen in all of the EEGs of newborn infants, but disappears entirely by 6 weeks.

FIGURE 3                      High voltage generalised slow activity typical of quiet sleep in a female aged 8 weeks (sedation by means of Vesparaxette suppository). AS is an abbreviation for auditory stimulus.

FIGURE 3

2. AS onset is replaced by QS onset. AS is the first sleep stage in about 80% of episodes in the first 3 weeks of life, but in only 5 - 10% by the 3rd month of life.
3. Decrease in amount of AS. During the first week of life, AS occupies about 50% of total sleep time, QS less than 50% and IS about 13%. By 8 weeks, AS has decreased to 20%, and QS has increased proportionately. Adults likewise spend about 20% of TST in REM sleep.

These findings emphasise the importance of the first two months of life as a period of rapid maturational flux in brain function. The importance of this period is further underscored by the results of a recent study by Crowell and his coworkers<sup>3</sup>, published at the beginning of this year. They found that infants at 3 months post-term have EEG features in daytime sleep, which together with EOG and EMG activity, signify the presence of sleep stages and their organisation resembling those in adults. Sleep regulatory mechanisms thus approach a level of functional maturity at 3 months in the human infant. This has implications for the clinical electroencephalographer, as a mature sleep pattern has usually been considered to emerge only at a much later age.

#### B. SPECIFIC SLEEP PHENOMENA (INCLUDING AROUSAL RESPONSES)

The characteristics of normal sleep phenomena are shown in Table 1. It must be emphasised that the specific phenomena of sleep spindles, vertex sharp transients, and K-complexes, the latter 2 referred to as arousal responses, are all normal. (Figure 4). Of relevance to the clinical electroencephalographer is that sleep spindles may show asymmetry and asynchrony between hemispheres well into childhood and still be normal. The development of sleep spindles can be seen in Figures 5 - 8. Vertex sharp transients appear with all degrees of sharpness in both normal and epileptic groups. Thus, even if their presence is characterised by high amplitude and spike-like format,

specific to sleep.

SLEEP SPINDLES

VERTEX SHARP TRANSIENTS

K-COMPLEXES

FIGURE 5                      Male, aged 8 weeks, sedated with Trichloryl.  
Poorly-developed sleep spindles are shown.  
Poor development of this waveform is seen in  
the excessive length of the spindles (upto 3,5  
seconds), a pronounced interhemispheric  
asymmetry with activity greater on the left and  
a relatively high frequency (14 Hz).

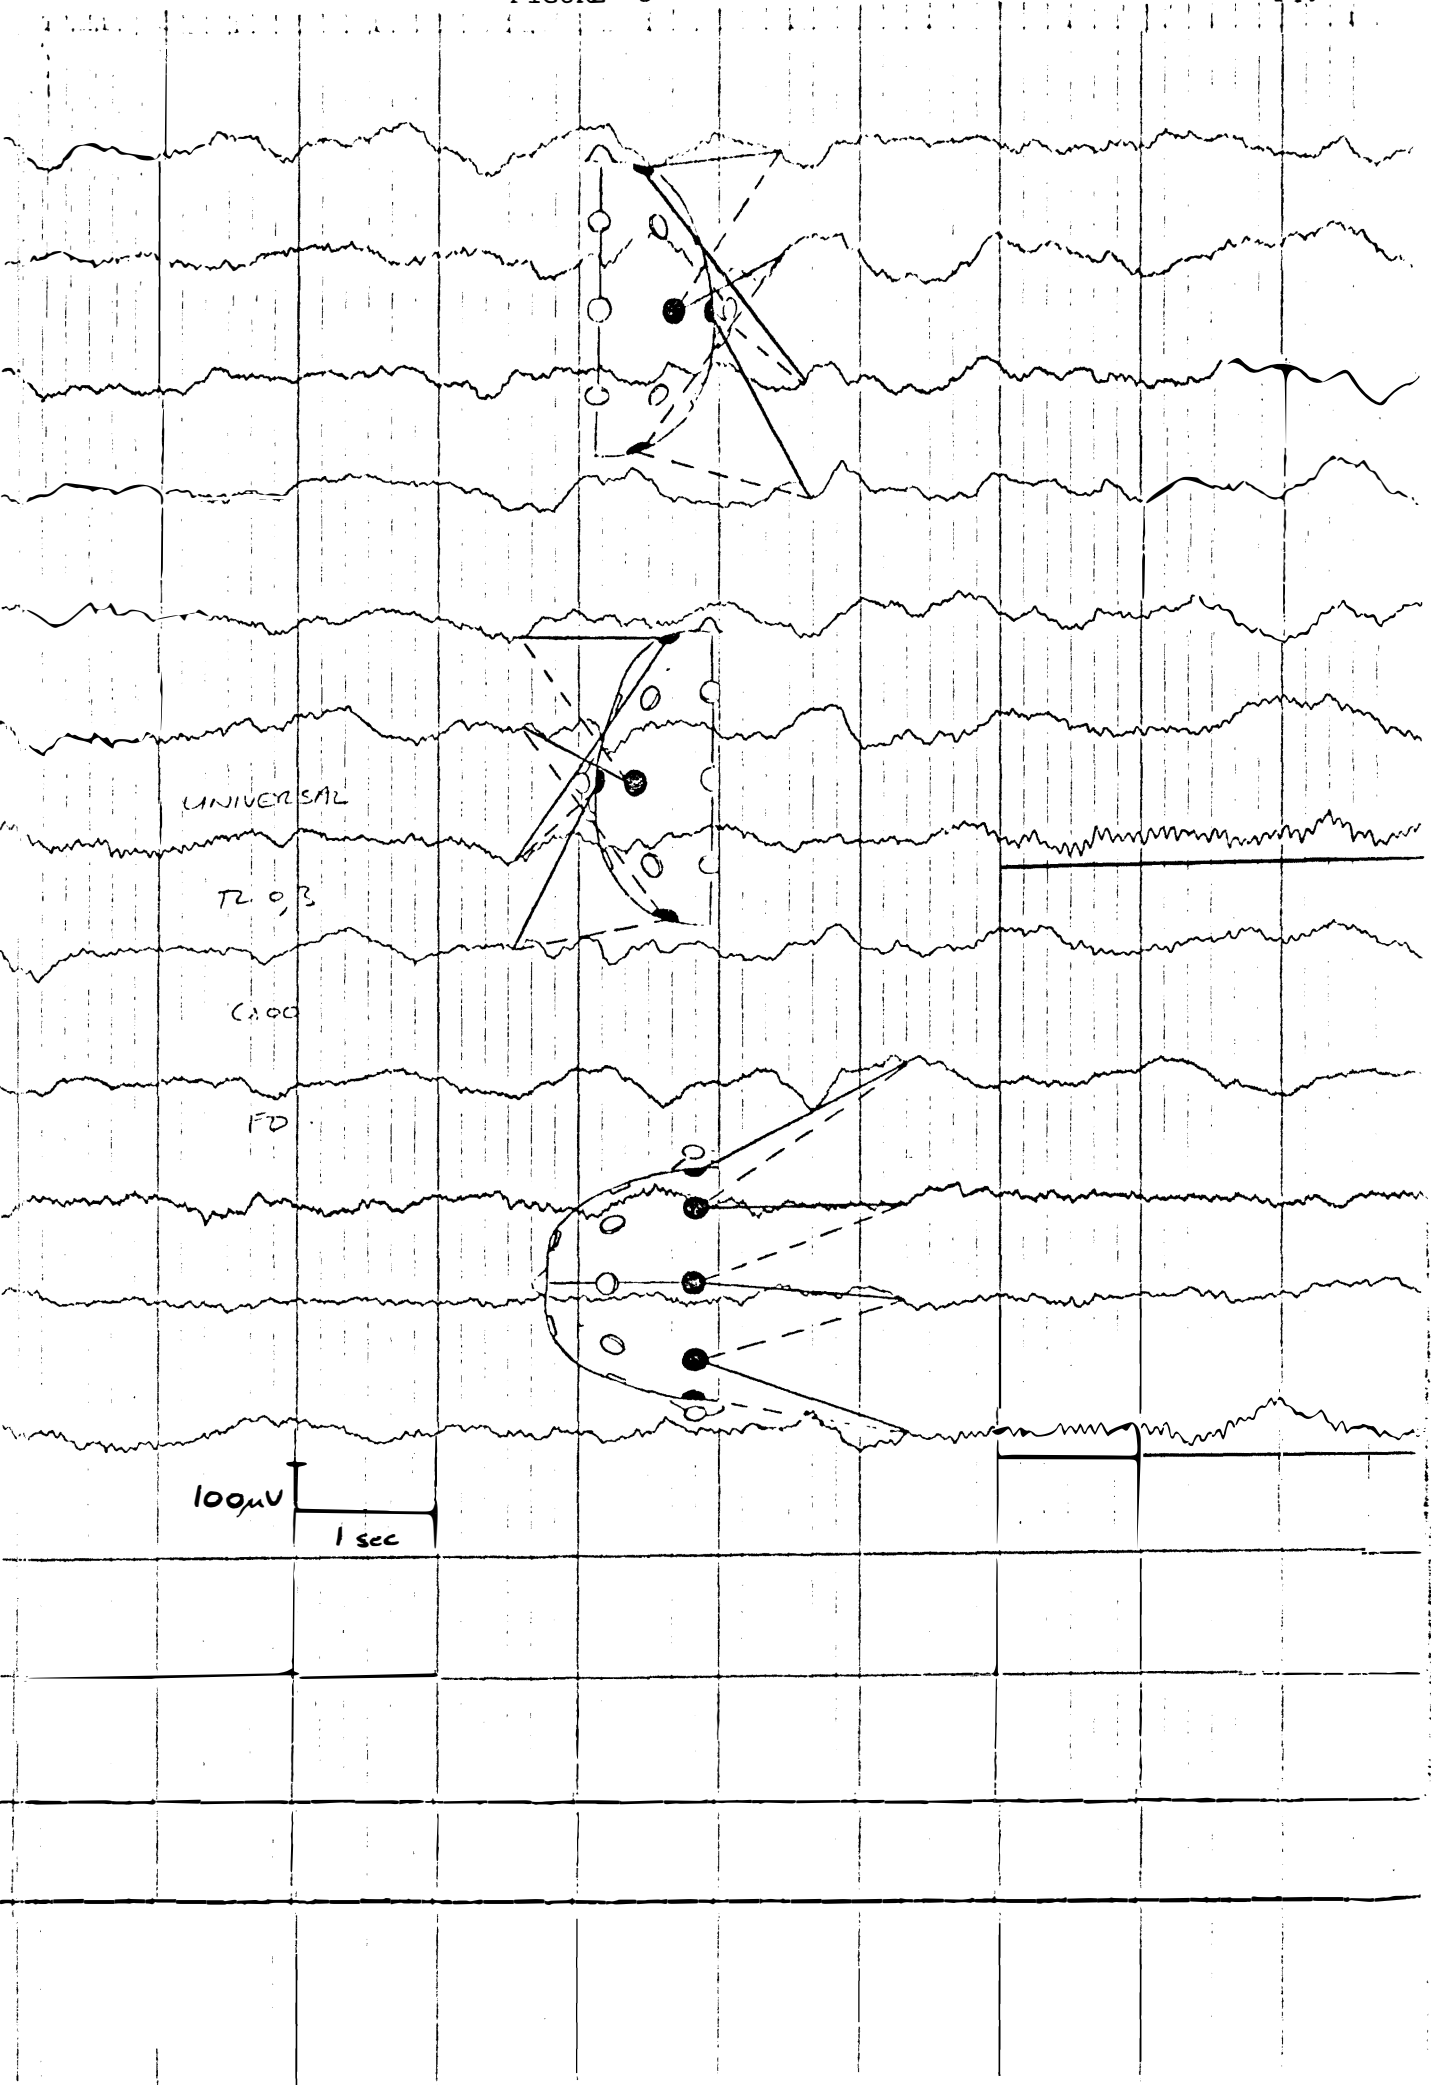

FIGURE 6                      Spindle activity in a male, aged 8 months.  
A more mature spindle form is shown with a  
relative symmetry of activity between hemis-  
pheres, in greater amplitude, shorter burst  
duration and a frequency of 13 Hz.  
Compare these parameters with those of  
Figure 5.

FIGURE 7

Spindle activity in a male, aged 17 months. Well developed spindles of short duration, frequency of 13 Hz, high degree of symmetry and relatively high voltage are shown. Compare with Figures 5 and 6.

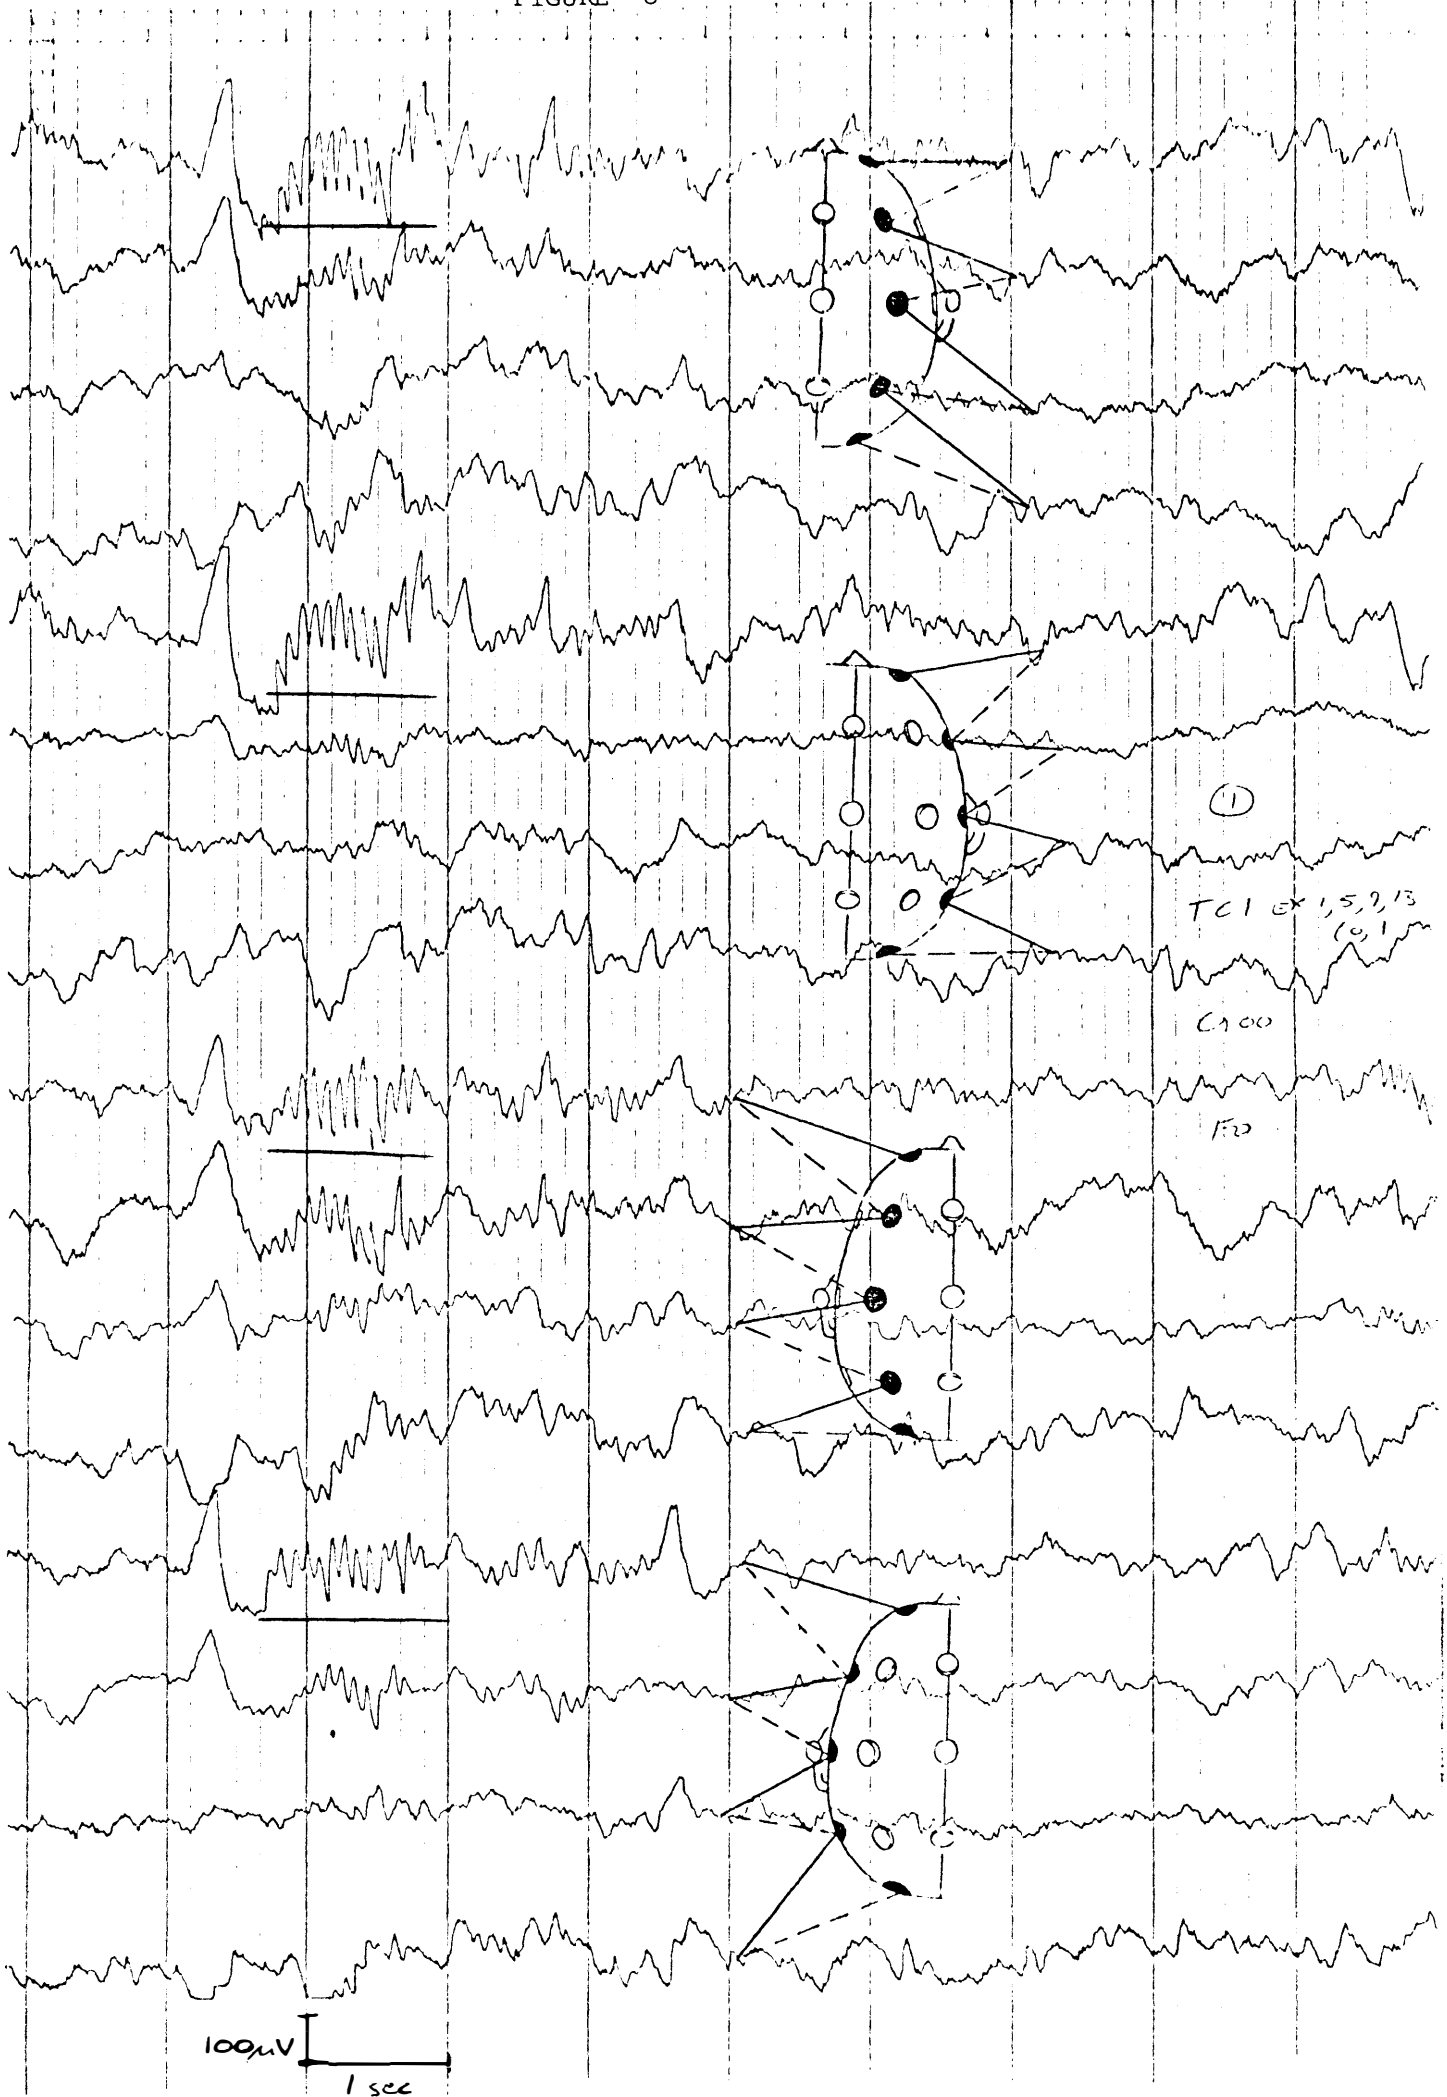

FIGURE 8                      Natural sleep in a male, aged 3 years 6 months.  
Short spindle bursts, symmetrical, with a high  
voltage and a frequency of 11 Hz occur.  
(Regular medication - Epanutin).

they should not be described as abnormal. Further, as the frequency, amplitude and paroxysmal morphology of K-complexes may easily be confounded with those of spike and wave activity, caution should be exercised in describing paroxysmal activity of this type as abnormal. (Figures 9 - 14). Of relevance to the decision as to whether burst or paroxysmal activity during sleep is abnormal, is the midline phase-reversal, and, in most cases, maximal amplitude affinity for the vertex, that these phenomena share. Thus, if a midline phase-reversal and/or vertex origin can be demonstrated for EEG activity of this type, a valid rule of thumb would appear to be to regard it as normal. This is demonstrated in Table 1 under location.

#### C. DROWSY HYPERSYNCHRONY

This, high voltage slow activity, often paroxysmal, may be associated with either pre- or post-sleep drowsiness. (Figure 15). It occurs in children up to the age of 5-6 years, and is maximal at the age of 1-2 years. It may be seen in children who, from all outward signs, appear awake. This is a potential error in interpretation, as paroxysmal activity in an awake child is usually regarded as epileptogenic. This type of activity should therefore be considered as normal unless definite spikes appear in association with it.

#### D. ENCOCHES FRONTALES

It has been shown (Ellingson and Peters, 1980a)<sup>4</sup> that random focal and multifocal sharp waves and spikes, often involving the frontal areas (the so-called 'encoches frontales') are frequently seen in the EEGs of full-term newborns. (Figure 16). This form of activity should therefore be interpreted conservatively. It should only be regarded as abnormal if it is highly repetitive or consistently focal. If this is so, this may signify an epileptogenic process.

FIGURE 9

Sleep in a female aged 7 weeks. A weak (poorly developed) vertex sharp transient occurs. Note the midline phase reversal and the relatively slow frequency of the transient.

FIGURE 10      Male, aged 8 weeks, sedated with Trichloryl.  
Two poorly-developed vertex sharp transients  
occur after auditory stimulation (clapping of  
hands).

W H A T I S A B N O R M A L ?

Dreyfus-Brisac and Curzi-Dascalova (1975)<sup>5</sup> state, as a general orientation: "From 3 to 12 months the presence of abnormal figures (focal spikes of any location, paroxysmal patterns of any kind) is very rare". (p6B - 27B). In spite of this, however, certain EEG patterns have been described as abnormal. A list of these is offered.

1. Lack of differentiation in the EEG between behavioural sleep and wakefulness. EEG changes from wakefulness to sleep have been noted in the 8 month (pre-term) foetus. Thus, if these changes are absent in the EEG of a full-term neonate, this is regarded as abnormal. Continuous slow (7 Hz) diffuse EEG activity during both sleep and wakefulness has been seen in neonates subjected to prolonged anoxia, and in microcephalic infants.
2. Disappearance of 'trace alternant'. Trace alternant activity has been described previously. This activity disappears in the EEGs of full-term neonates by 6 weeks of age. Once it is absent in the EEG of the individual case, it is not normally seen again. Persistence of this pattern beyond 6 weeks may signify a disturbance of cortical/subcortical relations. Ellingson and Peters (1980b)<sup>6</sup> found that trace alternant disappeared later in Trisomy 21 infants (mean of 57 days) than in normals (mean 33 days).
3. Asymmetry and asynchrony of sleep spindles. Due to considerable inter-individual variation in the symmetry and synchrony of sleep spindle bursts, Ellingson and Peters (1980a)<sup>7</sup> consider that only a complete unilateral or bilateral absence of spindles after the age of 3 months should be regarded as abnormal. Dreyfus-Brisac and Curzi-Dascalova (1975)<sup>8</sup> likewise feel that the absence of spindles between 3 and 8 months is a severe abnormality. Hypothyroid and hypoxic infants (Schultz et al (1968)<sup>9</sup>, for example,

showed delayed development of sleep spindles. It has been postulated that this is due to insufficient axon branching and synaptic contact. Sleep spindles also appeared significantly asymmetric and asynchronous as late as 12 months in Trisomy 21 infants, whereas normal full-term infants showed reasonable symmetry and synchrony as early as 3 months.

4. Hypsarrhythmia. The EEG is marked by high voltage poorly organised, multifocal or generalised spike/sharp wave and slow wave discharges. (Figure 17). The latter may occur with periods of intervening relative electrical silence (the burst - suppression pattern), or against a diffusely abnormal, slow background. (Figure 18). This type of activity is seen after the age of 4 months, and occurs up to the age of 4 years. It is associated with any diffuse insult to the maturing brain and suggests structural damage.
5. Focal spikes and spike and wave. Focal activity (phase reversed) is abnormal at any age. The problem for the electroencephalographer is whether phase reversed activity appears consistently enough to be described as focal. (Figures 19 - 21).

In general, Ellingson's (in Klass and Daly) (1979)<sup>10</sup> observations regarding neonatal EEGs appears to have general validity for those of sleeping infants as a whole: "They are difficult to evaluate, and there is no disgrace in sometimes having to equivocate. Less harm is done in confessing ignorance or indecision than in jumping to wrong conclusions".

#### SOME RECORDING CONSIDERATIONS

1. In very young infants, the head may be too small to accommodate a full electrode array. A limited number of electrodes must then be used and the question arises as to what array is most suitable. An important consideration is that at least one transverse series of electrodes should be used to assist the electroencephalographer to detect activity arising at the midline. This aids in determining whether paroxysmal activity may be classified as a specific sleep phenomenon or as epileptogenic.

FIGURE 17

Female, aged 11 months who presented with Salaam attacks. The sleep EEG showed high voltage poorly-organised multifocal spike and wave and spike and slow wave and sharp and slow wave discharges typical of hypsarrhythmia. Severely abnormal.

FIGURE 18      Sleep EEG in a male, aged 13 months, with cerebral palsy after possible foetal anoxia. The EEG shows a burst suppression pattern frequently seen in hypsarrhythmia. Severely abnormal.

FIGURE 19                      Sleep EEG (trichloryl) in a male, aged 2 years  
5 months with a history of tick bite fever.  
Focal left temporal spike discharges occur.  
Markedly abnormal.

FIGURE 19

FIGURE 20                      Sleep EEG (Vesparaxette) in a female, aged 3 years 5 months with a provisional diagnosis of epilepsy. Frequent spike discharges focal in the right centro-temporal area are shown. Markedly abnormal upholding diagnosis of epilepsy.

FIGURE 21                      Sleep EEG (Vesparaxette) in a female, 4 years and 4 months old. History of screaming episodes. Markedly abnormal EEG with spike and wave and multiple spike and wave activity appearing focally in the temporal and post-temporal areas.

2. The technician should be alert to, and note, any movements or activity on the part of the child. Especially important is to note any auditory stimuli in the environment. These in close association with paroxysmal activity in the EEG may prove crucial in the decision as to whether this is normal or epileptogenic. Further, the technician should attempt to rate the depth of sleep of the child during the course of the EEG.
3. If different electrode montages are employed, the technician should apply a standardised auditory stimulus (perhaps by tapping against the side of the EEG machine) during each. This allows later comparison of specific sleep phenomena obtained under standardised conditions.
4. A mundane consideration - allow extra time for sleep EEGs when making appointments, so that recordings of adequate length for the detection of abnormalities can be obtained.
